28 **Abstract**

29 Compounds from the nanotechnology industry, such as carbon-based nanomaterials, are strong
30 candidates to contaminate aquatic environments because their production and disposal have
31 exponentially grown in a few years. Previous evidence shows that fullerene C₆₀, a carbon
32 nanomaterial, can facilitate the intake of metals or PAHs both *in vivo* and *in vitro*, potentially
33 amplifying the deleterious effects of these toxicants in organisms. The present work aimed to
34 investigate the effects of fullerene C₆₀ in a *Danio rerio* (zebrafish) hepatocyte cell lineage exposed
35 to benzo[a]pyrene (BaP) in terms of cell viability, oxidative stress parameters and BaP intracellular
36 accumulation. Additionally, a computational docking was performed to investigate the interaction of
37 the fullerene C₆₀ molecule with the detoxificatory and antioxidant enzyme π GST. Fullerene C₆₀
38 provoked a significant ($p<0.05$) loss in cellular viability when co-exposed with BaP at 0.01, 0.1 and
39 1.0 $\mu\text{g/L}$, and induced an increase ($p<0.05$) in BaP accumulation in the cells after 3 and 4 hours of
40 exposure. The levels of reactive oxygen species (ROS) in the cells exposed to BaP were diminished
41 ($p<0.05$) by the fullerene addition, and the increase of the GST activity observed in the BaP-only
42 treated cells was reduced to the basal levels by co-exposure to fullerene. However, despite the
43 potential of the fullerene molecule to inhibit π GST activity, demonstrated by the computational
44 docking, the nanomaterial did not significantly ($p>0.05$) alter the enzyme activity when added to
45 GST purified extracts from the zebrafish hepatocyte cells. These results show that fullerene C₆₀ can
46 increase the intake of BaP into the cells, decreasing cell viability and impairing the detoxificatory
47 response by phase II enzymes, such as GST, and this latter effect should be occurring at the
48 transcriptional level.

1. Introduction

The fate of products and effluents from the nanotechnology industry has been a growing matter of concern because their production and disposal have exponentially risen in the last few years (Kahru and Dubourguier, 2010). The current data about the actual risks to humans and to the environment are not conclusive, and this is mainly due to the lack of information concerning their mechanisms of toxicity, actual concentrations and chemical behavior in the environment (Christian et al., 2008; Aschberger et al., 2011). However, the novel chemical and physical properties arising from the nanoscale greatly enhance the reactivity of the nanoparticles with biomolecules, making the nanomaterials potentially toxic and capable of harming the environment (Kahru and Dubourguier, 2010). On the other hand, it must also be considered that some works show low toxicity levels of carbon nanomaterials (such as fullerenes) in fish, at least with respect to oxidative stress parameters (Fraser et al., 2011; Henry et al., 2011).

Despite the debate concerning the actual toxicity level of the nanomaterials, especially in the aquatic environment, there is a consensus that nanomaterials may potentially affect biological systems not only *per se*, but also through interaction with other compounds (Christian et al., 2008; Henry et al., 2011). Considering their high reactivity, a question arises about what can happen when nanomaterials are in the presence of other toxic molecules. One of the first attempts to investigate this issue was conducted by Limbach et al. (2007), who measured the oxidative stress in human lung epithelial cells induced by nano-silica doped with a number of metals. This study found higher damage in the treatments with cobalt- and manganese-doped silica nanoparticles than in metals or silica alone. Because nano-silica facilitated the uptake of the metals by the cells, this mechanism was so-called the “Trojan horse” effect. This type of delivery mechanism displayed by nanomaterials has been investigated in a few additional nanotoxicological studies, mainly with metallic nanoparticles. For example, Fan et al. (2011) showed that nano-TiO₂ enhanced copper bioaccumulation and toxicity in the crustacean *Daphnia magna*, even at low nanomaterial concentrations. It was also found that nano-TiO₂ enhanced arsenate toxicity in *Ceriodaphnia dubia*

79 (Wang et al. 2011) and, when doped with the lanthanide Ce(IV), it caused deformation in the cell
80 morphology of a human hepatocyte cell line (Mao et al. 2010).

81 Studies investigating co-exposure with carbon-based nanocompounds, such as nanotubes and
82 fullerenes, are less common. Fullerene C₆₀ is a worldwide produced nanomaterial with a unique
83 cage-like molecular structure made solely of carbon. Although highly hydrophobic, due to its
84 electronic configuration it can form strong C₆₀-H₂O bonds when in colloidal water suspensions
85 (Andrievsky et al. 2002; Khokhryakov et al. 2006), resulting in stable nano-aggregates that can
86 promote deleterious effects in biological systems (Murdock et al. 2008; Ehrenberg et al. 2009).

87 C₆₀ has been widely investigated in terms of the chemical and physical interactions with a
88 range of molecules and devices looking for applications as nano-probes, nano-sensors and nano-
89 electrodes (Nakashima et al. 1998; Cho et al. 2005; Goyal et al. 2005) and in medicine (Partha et al.
90 2008; Pinteala et al. 2009; Ganji et al. 2010; Tarabukina et al. 2010; Adini et al. 2011; Santos et al.
91 2011). Despite being poorly studied, the uptake rate and toxicity of other environmental
92 contaminants seem to be somehow affected when co-exposed to fullerene. Baun et al. (2008)
93 indicated that co-exposure with fullerene C₆₀ enhanced the toxicity of phenanthrene to the
94 microcrustacean *Daphnia magna* and to the algae *Pseudokirchneriella subcapitata*. This was due, at
95 least in part, to the high adsorption of phenanthrene molecules onto C₆₀ nano-aggregates, which
96 facilitated phenanthrene uptake. Similarly, Costa et al. (2012) observed that arsenic (As^{III}) uptake
97 was higher in zebrafish hepatocytes co-exposed to fullerene (1 mg/L).

98 Among the polycyclic aromatic hydrocarbons (PAHs), benzo[a]pyrene (BaP) is one of the
99 most important due to its ubiquitous presence in most environments. It is produced mainly during
100 the incomplete combustion of organic matter and in cigarette smoke (Rose and Levi 2004). It is also
101 a carcinogen and mutagen toxicant and reactive oxygen species (ROS) generator (Sasco et al. 2004;
102 Naspinski et al. 2008). Its detoxification process includes metabolism by phase I enzymes that
103 can produce electrophilic epoxides that can readily bind to DNA (Walker et al. 2001). BaP
104 contamination can be harmful through the generation of oxidative stress (Palanikumar et al. 2012),

105 the inhibition of retinoids synthesis (Alsop et al. 2007) and the formation of DNA adducts (Kurelec
106 et al. 1991). The exposure of cultured cells to BaP can also cause changes in gene expression
107 (Castorena-Torres et al. 2008), oxidative impairment (Winzer et al. 2001) and an increase of the
108 carcinogenic risk by interaction with 17 β -estradiol (Chang et al. 2007), among many other
109 deleterious effects.

110 In order to investigate the influence of fullerene C₆₀ upon the toxicity of an important
111 environmental contaminant, such as BaP, the present work aimed to assess the oxidative stress
112 parameters, cell viability and bioaccumulation of BaP in ZF-L cells, an established culture of
113 hepatocytes from the zebrafish *Danio rerio* (Cyprinidae). This cell lineage was chosen because
114 *Danio rerio* is a highly suitable biological model widely used in toxicology, including in studies
115 with nanomaterials (Fako and Furgeson, 2009; Costa et al, 2012). Additionally, an *in silico* study
116 was performed by computational docking to verify the hypothesis of the interaction of the fullerene
117 C₆₀ molecule with the antioxidant and phase II detoxificatory enzyme glutathione-S-transferase
118 (GST).

119

120 2 Material and Methods

121

122 2.1 Preparation of the chemicals

123 2.1.1 Preparation and characterization of C₆₀ suspension

124 In order to produce a homogeneous suspension of C₆₀ nanoparticles, two hundred milligrams
125 of fullerene C₆₀ in powder form (99% purity, SES Research - USA) was added to 1 liter of ultra-
126 pure Milli-Q water and stirred for two months under artificial light. After this period, the suspension
127 was centrifuged at 25,000 x g and 15 °C for 1 hour to remove the bigger aggregates and was then
128 sequentially filtered by 0.45 and 0.20 μ m nylon membranes. This methodology was based on the
129 work of Lyon et al. (2006) where no organic solvent was employed because these solvents can
130 release residual degradation products that affect the toxicity of the nanomaterial (Henry et al.,

2007). The concentration of the suspension was determined by measurement of the total organic carbon content in a total organic carbon analyzer (TOC-V CPH – Shimadzu Corp. - Japan). The characterization of the C₆₀ suspension was performed by transmission electron microscopy (TEM) in a JEOL JSM 1200 EX II transmission electron microscope operating at 100 kV. For the TEM, aliquots of the C₆₀ suspension (10µl) were disposed onto 300 mesh TEM grids (SPI) that were coated with Formvar. The analysis was performed after 24 h to allow sample evaporation, according to previous studies (Britto et al., 2012; Costa et al., 2012; Ferreira et al., 2012). As previously reported for C₆₀ suspensions prepared using the water-stirring method without the addition of organic solvents (Lyon et al. 2006; Britto et al., 2012; Costa et al., 2012; Ferreira et al., 2012), the ubiquitous presence of fullerene nano-aggregates in the nanometer range were seen in the C₆₀ suspension analyzed by TEM (**Figure 1**).

142

143 **2.1.2 Preparation of BaP solutions**

144 BaP solutions ranging from 0.01 to 10.00 µg/mL were obtained by dissolving
145 benzo[a]pyrene (Fluka, purity ≥ 96%) in dimethyl sulfoxide (DMSO) (Synth, Brazil). The final
146 concentration of DMSO in contact with the cells was 1% since Filgueira et al. (2007) showed that
147 this DMSO concentration was not deleterious for an erythroleukemic cell line. In addition, the
148 DMSO control group showed no effects in the analyzed variables (see **Results**).

149

150 **2.2 Maintenance of the hepatocytes**

151 Zebrafish hepatocytes (ZF-L lineage) purchased from the American Type Culture Collection
152 (ATTC) were maintained in culture flasks with 10 mL of RPMI 1640 (Gibco) medium
153 supplemented with 10% fetal bovine serum and a 1% antibiotic/antimycotic cocktail (streptomycin,
154 amphotericin and penicillin) at 28 °C. For the exposure assays, cells were initially removed from
155 the flasks with 0.125% trypsin, washed with phosphate buffered saline (PBS) and transferred to 24-
156 well culture plates (0.5 mL per well, 10⁶ cells/mL) to settle down and adhere. After 24h, the cells

157 were carefully washed with PBS and exposed to the treatments.

158

159 **2.3 Experimental design and procedure**

160 All exposures were performed with at least 10^6 cells/mL in a final volume of 400 μ l per well
161 (toxicants or vehicles plus RPMI medium), with four wells per treatment at 28 °C over 4 h. After
162 this period, the cells were washed with PBS to remove the toxicants, and the estimation of the
163 number of cells was performed, as well as the cell viability assay (see next section). Initially, some
164 assays were conducted with a range of concentrations of both C₆₀ (0.1, 1.0 and 10.0 mg/L) or BaP
165 alone (from 0.01 to 10.0 μ g/L) in order to determine the optimal concentrations for which the cell
166 viability was not altered. Because none of the fullerene concentrations altered the cell viability (see
167 **Results** section) and considering previous exposure studies (Costa et al. 2012), the concentration of
168 1.00 mg/L of C₆₀ was chosen for the further co-exposures with BaP. BaP concentrations of 0.01,
169 0.10 and 1.0 μ g/L were chosen for the subsequent exposures because they did not impair hepatocyte
170 viability. Control groups included a Milli Q water control (the solvent of the fullerene suspensions)
171 and a DMSO control (BaP solvent) at a final concentration of 1%.

172

173 **2.4 Estimation of number of cells and viability assays**

174 Four control wells (800 μ l of cell suspension) from the 24-well plate were pooled and
175 diluted with RPMI medium to obtain aliquots of 100%, 75%, 50% and 25% of the original cell
176 suspension. After that, the cells were counted in an optical light microscope, and 200 μ l of the
177 dilutions were read in duplicate at 630 nm with an ELISA microplate reader (Biotek Elx 800). The
178 absorbance values were then fitted to the respective number of cells previously counted in the
179 microscope, and a standard curve was made to estimate the number of cells of the treatments after
180 reading at 630 nm (Costa et al. 2012).

181 The technique of intracellular reduction of 2-(4,5-dimethyl-2-thiazolyl)-3,5-diphenyl-2H-
182 tetrazolium bromide (MTT) to formazan by mitochondrial dehydrogenase activity was employed

183 for the cell viability measurement. Aliquots of 20 μ l of cell suspensions were added in 96-well
184 plates and incubated for 30 min in the dark at 28 °C with 20 μ l of a 12 mM MTT solution.
185 Following the incubation, the plate was centrifuged for 7 min at 1,100 rpm, the supernatant was
186 discarded and 200 μ l of DMSO was added to dissolve the blue formazan crystals. Finally, the
187 samples were read at 490 nm in an ELISA microplate reader. The absorbance values were
188 considered as a measure of dehydrogenase functionality and, therefore, an indirect cell viability
189 parameter (Costa et al. 2012).

190

191 **2.5 Determination of the ROS concentration**

192 Following the exposure, the hepatocytes were centrifuged at 600 x g for 5 min at 10 °C, the
193 supernatant was discarded and the cells were re-suspended in a solution with 40 μ M of the
194 fluorescent probe 2,7'-dichlorodihydrofluorescein diacetate (H₂DCF-DA, Invitrogen) in PBS.
195 Immediately, the cell suspension was transferred to a white 96-well microplate (160 μ l per well in
196 triplicate) and read in a microplate reader fluorimeter (Victor 2, Perkin Elmer) at wavelengths of
197 485 and 520 nm for the excitation and emission, respectively. The ROS concentration was
198 expressed in terms of fluorescence area resulting from the integration of the fluorescence values
199 between 0 and 70 min after fitting to a second order polynomial. The ROS area was fitted to the
200 estimated cells number in each treatment (Costa et al. 2012).

201

202 **2.6 Glutathione-S-transferase (GST) activity assay**

203 The activity of the phase II enzyme GST was determined through the monitoring of a
204 conjugate formed by 1 mM of reduced glutathione (GSH) and 1 mM of 1-chloro-2,4-dinitrobenzene
205 (CDNB) (Sigma) in the presence of 100 μ l of cell extract in PBS at 340 nm (Habig and Jakoby,
206 1981). The results were expressed as nanomoles of GSH-CDNB conjugate/min/mg protein at 25 °C
207 and pH 7.40. The total protein content was assessed through a commercial kit (Doles, Brazil) based
208 on the pirogalol method.

209

210 **2.7 Quantification of the BaP concentration in the BaP working solutions**

211 The PAH analyses were conducted using a gas chromatograph coupled with a mass
212 spectrometer (Perkin Elmer[®] Clarus 500 – GC-MS) and equipped with an Elite-5MS silica capillary
213 column (Perkin Elmer[®] 5% phenyl-95% methylpolysiloxane; 30 m x 0.25 mm, 0.25 µm film
214 thickness). The injector was kept at 280 °C in splitless mode. The temperature program started at 40
215 °C, increased at a rate of 10 °C min⁻¹ to 60 °C, then increased at 5 °C min⁻¹ to 290 °C, was
216 maintained at 290 °C for 5 minutes and then increased at 10 °C min⁻¹ to 300 °C and was held
217 constant for 10 minutes. Helium was used as the carrier gas (1.5 mL min⁻¹). The MS operating
218 conditions were: interface at 290 °C, ion source at 200 °C and electron energy of 70 eV. The data
219 were acquired under selected ion monitoring (SIM) mode. Compound identification was based on
220 the individual mass spectra and the GC retention time in comparison to literature, library data, and
221 authentic standards. Standards were injected and analyzed under the same conditions as the
222 samples. The limit of detection (LOD) of BaP was in the range of 1.75 ng mL⁻¹, and the limit of
223 quantification (LOQ) was 5 ng mL⁻¹. The procedure was checked for recovery efficiencies by
224 analyzing uncontaminated samples spiked with BaP standards. The average recoveries (n=5) ranged
225 from 88% to 101%. PAH surrogate standards (p-therphenyl-d14) were added to all samples to
226 monitor the procedures of sample extraction, recovery and analysis. The average recoveries of the
227 surrogate standards added samples varied from 91 % to 117%. One laboratory blank and one
228 duplicate were run with every 10 samples. The coefficient of variation of the BaP concentrations in
229 the duplicates was less than 15%. Still, to evaluate the precision of the analysis, two replicates of
230 the samples were analyzed. The relative standard deviation (RSD) of the replicates varied between
231 2 and 5%. Regular analyses of the reference material from the International Atomic Energy Agency
232 Analytical Quality Control Services (Organic Contaminants in Marine Sediment - IAEA-417) and
233 semiannual participation in the intercomparison exercises promoted by the Canadian Association
234 for Laboratory Accreditation (CALA) have shown satisfactory quality control. The measured

235 concentrations confirmed that the nominal concentration (1,000 ng/mL) was within $1,018 \pm 30.0$
236 ng/mL.

237

238 **2.8 Estimation of BaP intracellular accumulation**

239 The BaP (or its metabolites) intracellular accumulation (1.0 $\mu\text{g/L}$) over time (1, 2, 3 and 4 h
240 of incubation) with and without co-exposure to C_{60} (1.0 mg/L) was assessed following the protocol
241 described by Filgueira et al. (2007). The readings were performed after washing the cells with PBS,
242 and aliquots of 160 μL were put in a white 96-well plate to read in a fluorimeter at the wavelengths
243 of 340 and 450 nm for excitation and emission, respectively.

244

245 **2.9 *In silico* assay of the interaction of fullerene C_{60} molecule with π GST**

246 Due to the results obtained in the GST activity assay (see **Results** section), a mathematical
247 simulation (computational docking) of the interaction between the molecules of C_{60} and GST was
248 performed to investigate the potential affinity of the fullerene C_{60} for GST enzyme, which could
249 interfere with the enzymatic activity. For this simulation, the class pi mitochondrial GST (π GST)
250 was chosen as the model for the C_{60} docking. This isoform was selected due to the high number of
251 mitochondria present in hepatocytes, the availability of computational data from a mouse liver π
252 GST, which possess a good analogy with the zebrafish π GST, and the recent evidence of the role of
253 π GST in BaP detoxification in zebrafish (Garner and Di Giulio, 2012). The docking simulations of
254 the fullerene with mouse liver π GST complexed with S-(P-nitrobenzyl) glutathione (PDB code
255 1GLQ) were performed using AutoDock Vina 1.1.1 [1] followed by redocking with AutoDock
256 4.0.1. Before the simulations, the inhibitor S-(P-nitrobenzyl) glutathione was removed from the
257 structure, and the enzyme was geometrically optimized using the Universal Force Field (UFF)
258 implemented in the Avogadro 0.9 software. The fullerene molecule was constructed in Avogadro,
259 and its geometry was optimized using UFF. The enzyme was kept in its catalytic (dimeric) form.
260 AutoDock Tools was used to create the inputs in the .pdbqt format for the simulations in AutoDock

261 Vina. A second docking was made using AutoDock to confirm the data obtained by AutoDock Vina.
262 The entire system was considered for the simulations. The grid box was centralized at the
263 coordinates $x = 63.504$, $y = 18.195$ and $z = 5.743$, with dimensions of 60, 60 and 60 Å using a
264 spacing of 1 Å and the exhaustiveness set to 50. All other parameters were used as defaults. The
265 conformation with the lowest binding free energy was accepted as the best affinity model. The
266 conformations and interactions were analyzed using the software Accelrys Discovery Studio
267 Visualizer 2.5 and PyMOL. A redocking was conducted using the S-(P-nitrobenzyl) glutathione to
268 validate the method. In this case, the molecule was successfully positioned at a similar position to
269 the crystallographic conformation, with an RMSD less than 1.

270

271 **2.10 Verification of the effect of C₆₀ on the activity of GST in purified extracts**

272 Based on the results from the docking assay, and in order to investigate whether the
273 modulation of GST activity observed in the treatments BaP+C₆₀ was induced by the direct
274 interaction of the nanomaterial with the enzyme (see **Results** section), an *in vitro* assay was run in
275 which the GST activity was measured in GST purified extracts previously exposed to C₆₀. The
276 purified extracts of GST from ZF-L cells were obtained through a commercial kit (MagneGST[®],
277 Promega), and the procedure was followed according to manufacturer's instructions. The method is
278 based on the binding of glutathione-conjugated magnetic particles with GST enzymes present in the
279 samples, which allows for the separation of these enzymes from the rest of the cellular extract. Once
280 the purified extracts were obtained, an exposure assay was performed in which the GST extracts
281 were mixed with 10 mg/L fullerene C₆₀ over 4 h at 28 °C in the absence of light. After the exposure,
282 a GST activity assay was performed identically to the method described in **Section 2.6**.

283

284 **2.11 Statistical analysis**

285 Data from all assays were analyzed by means of ANOVA (Zar, 1984) after the verification of
286 normality and homogeneity of variances; if even one of the assumptions was violated, mathematical

transformations were applied. Post-hoc comparisons among the treatments were performed through the Newmann-Keuls method, and a significance level of 0.05 was adopted for all steps of the analysis.

290

3 Results

Because the cell viability was not significantly ($p>0.05$) reduced by any of the three tested C_{60} aggregates (**Figure 2a**), and based on previous evidence of oxidative balance disturbance in fish, both *in vivo* (Oberdörster 2004) and in ZF-L cultured cells (Costa et al. 2012), a concentration of 1.0 mg/L was adopted for the subsequent co-exposures with BaP. BaP, however, was capable of reducing cell viability ($p<0.05$) at 10.0 $\mu\text{g/L}$ (**Figure 2b**), thus the concentrations of 0.01, 0.1 and 1.0 $\mu\text{g/L}$ were chosen for co-exposure to C_{60} . At those BaP concentrations, fullerene C_{60} significantly ($p<0.05$) lowered the cell viability during co-exposure experiments (**Figure 3**).

299

The exposure to 1.00 $\mu\text{g/L}$ of BaP resulted in an augmented intracellular accumulation of BaP (or its metabolites) in ZF-L cells only when co-exposed to fullerene C_{60} (**Figure 4a**). The longer the incubation time was, the higher the accumulation values ($p<0.05$). **Figure 4b** shows the fluorescence units in the blank samples (without cells), demonstrating that C_{60} did not interfere ($p>0.05$) with the readings at the wavelengths used for the BaP accumulation measurements.

Figure 5 shows the levels of intracellular ROS of the exposed ZF-L cells. The BaP-only treatments did not significantly ($p>0.05$) increase the ROS generation when compared to the respective controls. On the contrary, the co-exposure with C_{60} decreased ($p<0.05$) the basal ROS level.

The activity of the phase II enzyme GST increased ($p<0.05$) after exposure to 0.10 and 1.00 $\mu\text{g/L}$ of BaP (**Figure 6**). However, the co-exposure to C_{60} reversed the GST activity to its basal levels despite the presence of BaP.

Figure 7 shows a 3D representation from the docking simulation of the C_{60} in the π GST

313 molecule. The results showed that the fullerene C₆₀, in its more stable conformation (Gibbs free
314 energy: -11.5 kcal/mol), was situated at a region of the enzyme postulated as the binding site of
315 HEPES, near the C-terminal region between the elements β2 and α1. This region, due to the
316 presence of the amino acids Arg18, Ala22, Trp28 and Phe192, produces a hydrophobic surface that
317 favors fullerene binding stabilization through Van der Waals forces (Figure 7b). Moreover, the data
318 revealed that fullerene acts via three cation-π type interactions with the residual Lys188, and such
319 interactions seem to be the main force contributing to the affinity of the nanomaterial with the
320 HEPES binding site of π GST.

321 The exposure of the ZF-L purified extracts to 10 mg/L of C₆₀ for 4 h had no effect on the
322 GST activity (p>0.05). The Control groups produced 12.95 ± 4.38 nanomoles of GSH-CDNB
323 conjugate/min/mg protein, whereas the C₆₀ groups produced 14.13 ± 4.22 nanomoles of GSH-
324 CDNB conjugate/min/mg protein.

325

326 **4 Discussion**

327 Fullerene toxicity is a controversial issue. Kahru and Dubourguier (2010) compiled fullerene
328 toxicological data for fourteen organisms and classified this nanomaterial as very toxic, taking into
329 account the lowest median L(E)C₅₀ values for all test organisms. However, some studies indicate
330 the absence of fullerene toxicity (i.e., Xia et al. 2010), whereas others considered that ROS
331 generation by aqueous fullerene suspension is minimal (i.e., Henry et al., 2011). Recently, Trpkovic
332 et al. (2012) stated that fullerene toxicity can be elicited by ROS-dependent (when photo-excited)
333 and ROS-independent mechanisms, where the latter is considered to be through cell membrane
334 damage and/or induction of autophagy. An ROS-independent pathway should be considered
335 responsible for the cytotoxicity observed in the present study because fullerene and BaP exposures
336 were performed in incubators in the dark at 28 °C.

337 Yang et al. (2010) raised the possibility of aqueous fullerene suspensions acting similarly to
338 dissolved organic matter (DOM), changing the bioavailability of toxic molecules (such as PAH).

339 This concept was related to the ‘Trojan horse’ paradigm first postulated by Limbach et al. (2007). In
340 addition, Henry et al. (2011) highlighted the potential environmental risk of fullerene due to its
341 capacity to act as a carrier for other contaminants. However, the “Trojan horse’ concept needs to be
342 better studied. The original paper of Limbach et al. (2007) compared the levels of intracellular ROS
343 between silica nanoparticles containing metals and the corresponding oxides. Other authors, such as
344 Baun et al. (2008), considered the “Trojan horse’ effect under the view of the augmented
345 accumulation of a toxic molecule (as phenanthrene) when co-exposed with a nanomaterial, such as
346 fullerene, and the toxicological consequences of this co-exposure. The same concept was
347 considered by Sun et al. (2009), in terms of arsenic accumulation in carp gills after co-exposure
348 with titanium dioxide nanoparticles, and by Costa et al. (2012) studying arsenic accumulation in
349 zebrafish hepatocytes after co-exposure to fullerene. Following the postulation of Baun et al.
350 (2008), the present work demonstrated the deleterious effects and higher accumulation of BaP (or
351 its metabolites) when co-exposed with fullerene C₆₀ and the consequences in terms of cytotoxicity,
352 intracellular ROS and detoxification capacity.

353 The effects of mixtures of pollutants in the environment are usually hard to predict due to
354 many factors. This task is even more difficult when nanomaterials are under study in virtue of their
355 inherent properties, which can amplify or alleviate the toxic effects of other compounds. To the best
356 of our knowledge, information about the influence of the physical-chemical characteristics of toxic
357 molecules on nanomaterial interactions is currently lacking. Fullerene C₆₀ has induced loss in cell
358 viability when co-exposed with BaP, which did not occur with cells treated with BaP only (**Figure**
359 **3**). This result is probably due to the increase of the BaP intracellular accumulation caused by
360 fullerene C₆₀ (**Figure 6**). Once a higher BaP concentration is inside the cells, the increasing damage
361 may lead to the observed loss in the mitochondrial dehydrogenase functionality, as measured by the
362 MTT assay. This finding is in accordance with the work of Baun et al. (2008), as mentioned above.
363 Al-Subiai et al. (2012) registered higher genotoxicity in mussel haemocytes when fluoroanthene
364 and fullerene were co-exposed. However, this is not always true. Yan et al. (2010) reported lower

365 histological damage induced by fluoroanthene when co-exposed with fullerene under UV radiation,
366 and Baun et al. (2008) observed that fullerene did not influence the toxicity of atrazine and methyl
367 parathion to the algae *P. subcapitata* and the crustacean *D. magna*.

368 The presence of fullerene C₆₀ reduced the intracellular concentration of ROS (**Figure 4**),
369 resulting in an antioxidant effect. This may be due to the low number of viable cells in BaP+C₆₀
370 treatments or to the ability to react with radicals, which is attributed to the C₆₀ molecule
371 (Andrievsky et al. 2009; Xia et al. 2010). This property is postulated as a non-stoichiometric
372 reaction, in which a self-neutralization could occur when the molecule is in a hydrated state, and it
373 could give the observed scavenging characteristics to the nanomaterial (Andrievsky et al. 2009).
374 Previous studies from our group employing cell suspension from carp *Cyprinus carpio* brains
375 registered a reduction of intracellular ROS after 2 h of exposure to 1 mg/L of fullerene, also
376 showing an antioxidant behavior of an aqueous suspension of this nanomaterial (Acosta et al.,
377 2012).

378 The activity of the total GST was raised in the BaP-only treatments, which is a classical
379 effect of this PAH and is associated to the generation of ROS (Vieira et al. 2008; Palanikumar et al.
380 2012). Interestingly, co-exposure to C₆₀ hinders this increase, keeping the enzyme activity at the
381 basal levels (**Figure 6**), a result that can be deleterious for cell viability (as observed) because of the
382 lowering of the detoxifying capacity. Moreover, the computational docking showed that the C₆₀
383 molecule can potentially affect the GST activity because of its affinity for a hydrophobic region of π
384 GST, which is postulated as an allosteric site of HEPES. Such interaction may alter the C terminal
385 region of the enzyme, producing conformational changes that can modify the xenobiotic binding
386 site (Ji et al. 1997). From a toxicological point of view, this evidence is relevant because it
387 demonstrates that fullerene C₆₀ can induce deleterious effects by impairing important detoxificatory
388 responses, such as the phase II mechanisms.

389 However, the nanomaterial did not affect the enzyme activity in the GST purified extracts of
390 ZF-L cells, even at a concentration of 10 mg/l. A possible explanation is that, although the molecule

391 of fullerene has the potential to inhibit π GST activity, it could not bind to the allosteric site of
392 HEPES due to the nanoparticle size, which is a consequence of the aggregation state of fullerene
393 (an aspect not considered in the docking analysis). The lack of effects in the purified extracts in
394 terms of the inhibition of GST activity contrasts with the cell assays, where a clear inhibition of this
395 enzyme was observed, suggesting that the deleterious effects of fullerene may be occurring at the
396 transcriptional level. Schlenk et al. (2008) stated that GST enzymes are more abundant in the liver,
397 being the π -class homolog the predominant form in cyprinids. In this way, although 1-chloro-2,4-
398 dinitrobenzene (CDNB) is a substrate for several GST isoforms (Schlenk et al., 2008), it is expected
399 that the measured activity should reflect the catalytic activity of the π isoform when measured in
400 zebrafish hepatocytes.

401 Mashino et al. (2001) proved in a previous study that fullerene functionalized with
402 carboxylic groups inhibited glutathione reductase, another enzyme that has glutathione as co-
403 substrate. Thus, both the agglomeration of fullerene molecules in the aqueous suspension and the
404 fact that the nanomaterial was in a non-functionalized form should explain the lack of inhibitory
405 potency in the assays with purified extracts and suggests indirect toxicity mechanism(s). At the
406 present, the hypothesis of the role of the fullerene as a down-regulator of GST transcription is being
407 analyzed at our laboratory.

408

409 **5 Conclusions**

410 Altogether, the results show that fullerene elicited toxic effects in ZF-L cells by increasing
411 the intake of BaP, decreasing cell viability and impairing the detoxificatory response by the phase II
412 enzyme GST. This latter effect probably occurs at the transcriptional level. The potential affinity of
413 fullerene to π GST needs further investigation, since this isoform is postulated as the predominant
414 GST class in cyprinids.

415

416 **Conflict of interest statement**

417 The authors declare that there are no actual or potential conflicts of interest in the present
418 work.

638 **Figure Captions**

639

640 **Figure 1.** Transmission electron microscopy (TEM) image of fullerene C₆₀ from the suspension
641 obtained by the solvent-free method.

642

643 **Figure 2.** Cell viability measurement after 4 h of exposure employing the method of reduction of
644 MTT by mitochondrial dehydrogenases. **C:** Milli Q water control. **D:** dimethyl sulfoxide (DMSO)
645 control. **(a)** Percentage of viable cells exposed to fullerene C₆₀ (0.1, 1.0 or 10.0 mg/L). **(b)**
646 Percentage of viable cells exposed to BaP (0.01, 0.1, 1.0, or 10.0 µg/L). N= 4 to 16 independent
647 experiments.

648

649 **Figure 3.** Absorbance values of MTT reduction in cells treated with BaP (0.01, 0.10 or 1.0 µg/L)
650 with or without fullerene C₆₀ (1.0 mg/L). **C:** Milli Q water control. **D:** dimethyl sulfoxide (DMSO).
651 Same letters indicate the absence of statistically significant (p>0.05) differences. N= 4 to 8
652 independent experiments.

653

654 **Figure 4.** Intracellular accumulation of BaP in ZF-L cells exposed to BaP with or without fullerene
655 C₆₀ (1.0mg/L). **C:** Milli Q water control. **D:** dimethyl sulfoxide (DMSO) control. **(a)** Accumulation
656 kinetics of BaP (1.00 µg/L) throughout 4 h of exposure; data are expressed as percentages of the
657 control group. **(b)** Fluorescence units from the readings in samples without cells after 4 h of
658 incubation to BaP (0.01, 0.10 or 1.00 µg/L). Same letters indicate the absence of statistically
659 significant (p>0.05) differences. N= 3 to 4 independent experiments.

660

661 **Figure 5.** Reactive oxygen species (ROS) concentration after 4 h of exposure to BaP (0.01, 0.10 or
662 1.00 µg/L) with or without fullerene C₆₀ (1.0 mg/L). **C:** Milli Q water control. **D:** dimethyl sulfoxide
663 (DMSO) control. Data are expressed as relative fluorescence area adjusted to the number of viable

664 cells of each treatment. Same letters indicate the absence of statistically significant ($p>0.05$)
665 differences. N= 3 to 4 independent experiments.

666

667 **Figure 6.** Specific activity of glutathione-S-transferase (GST) in ZF-L cells exposed for 4 h to BaP
668 (0.01, 0.10 or 1.00 $\mu\text{g/L}$) with or without fullerene C_{60} (1.0 mg/L). **C:** Milli Q water control. **D:**
669 dimethyl sulfoxide (DMSO) control. Same letters indicate the absence of statistically significant
670 ($p>0.05$) differences. N= 3 to 8 independent experiments.

671

672 **Figure 7. (a)** Scheme of pi glutathione-S-transferase (GST) isoform, showing the binding site of
673 glutathione and the HEPES allosteric site where fullerene C_{60} showed the highest affinity. **(b)**
674 Amino acid residues close to fullerene C_{60} . The model shows the interaction with lysine residue
675 188.

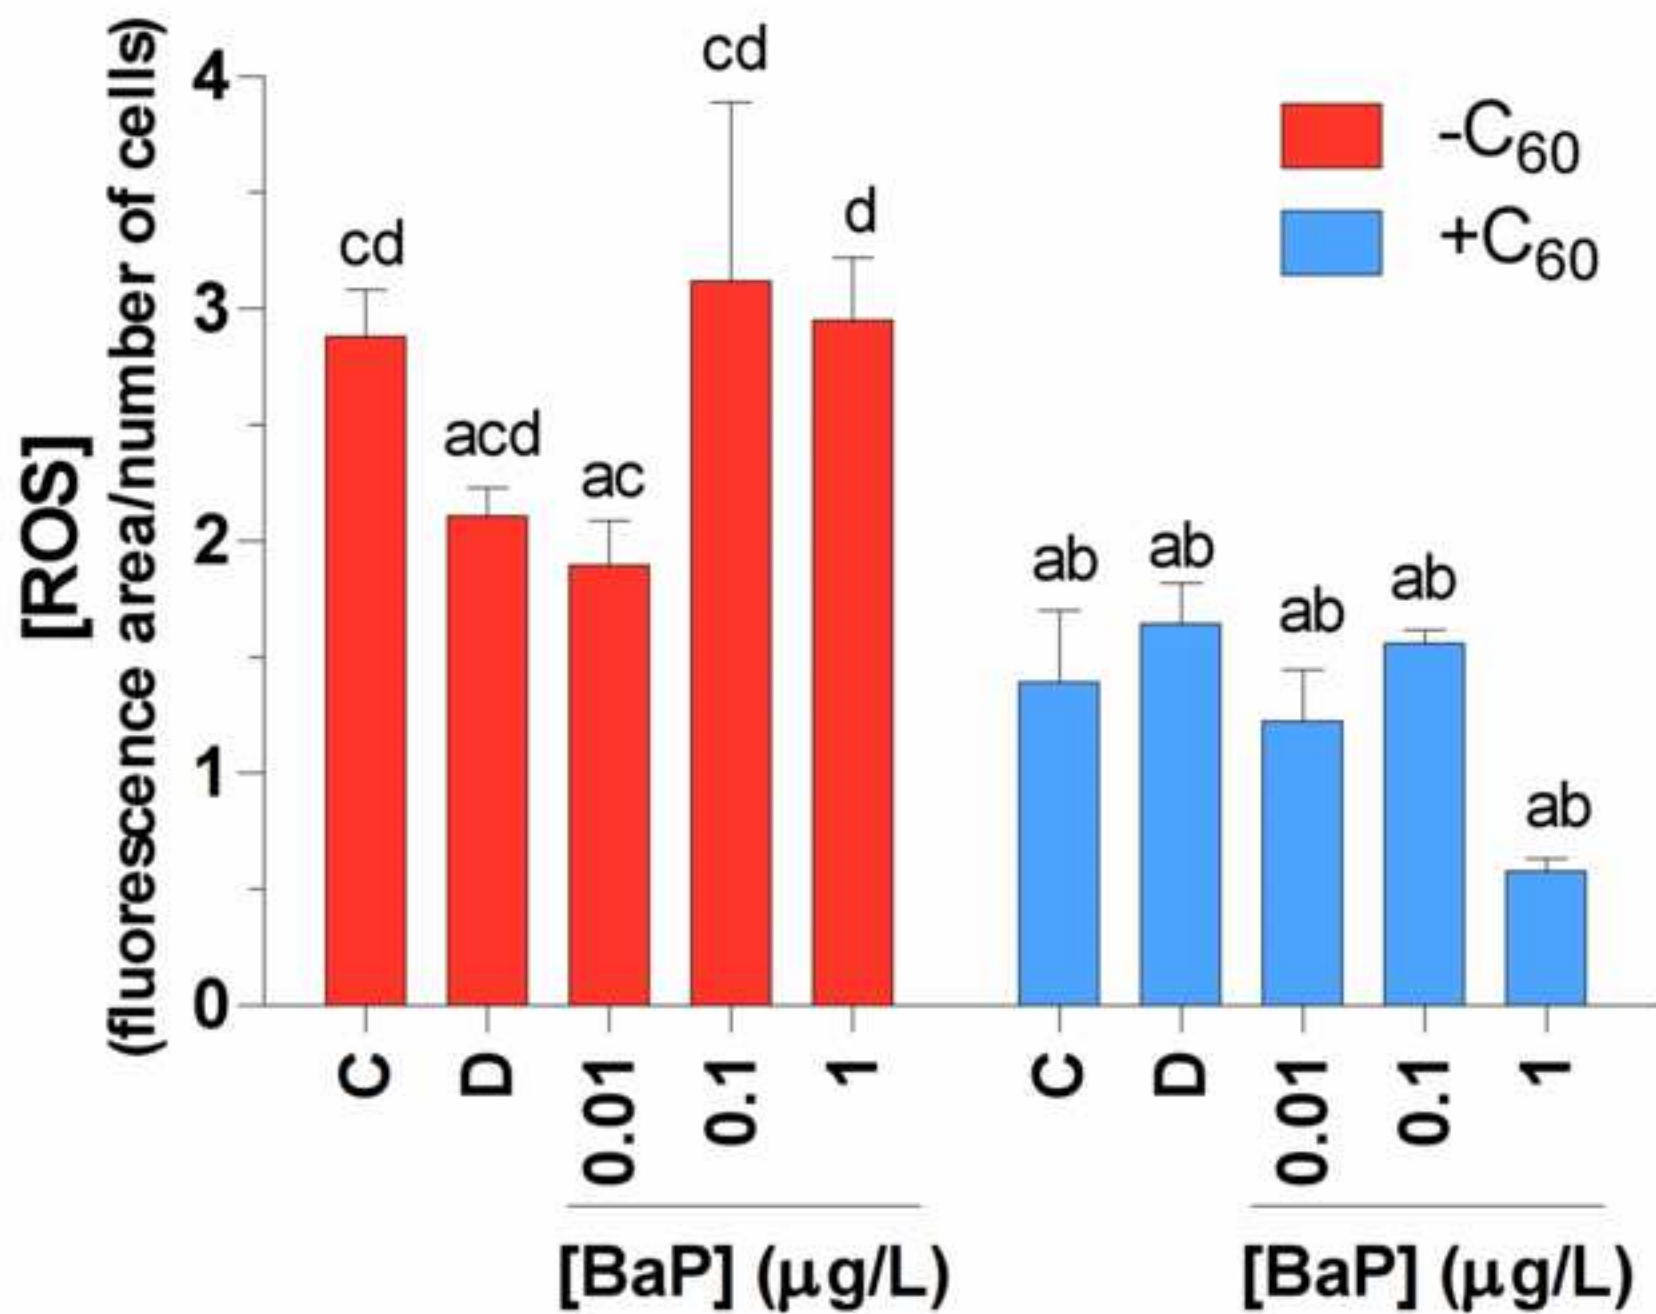

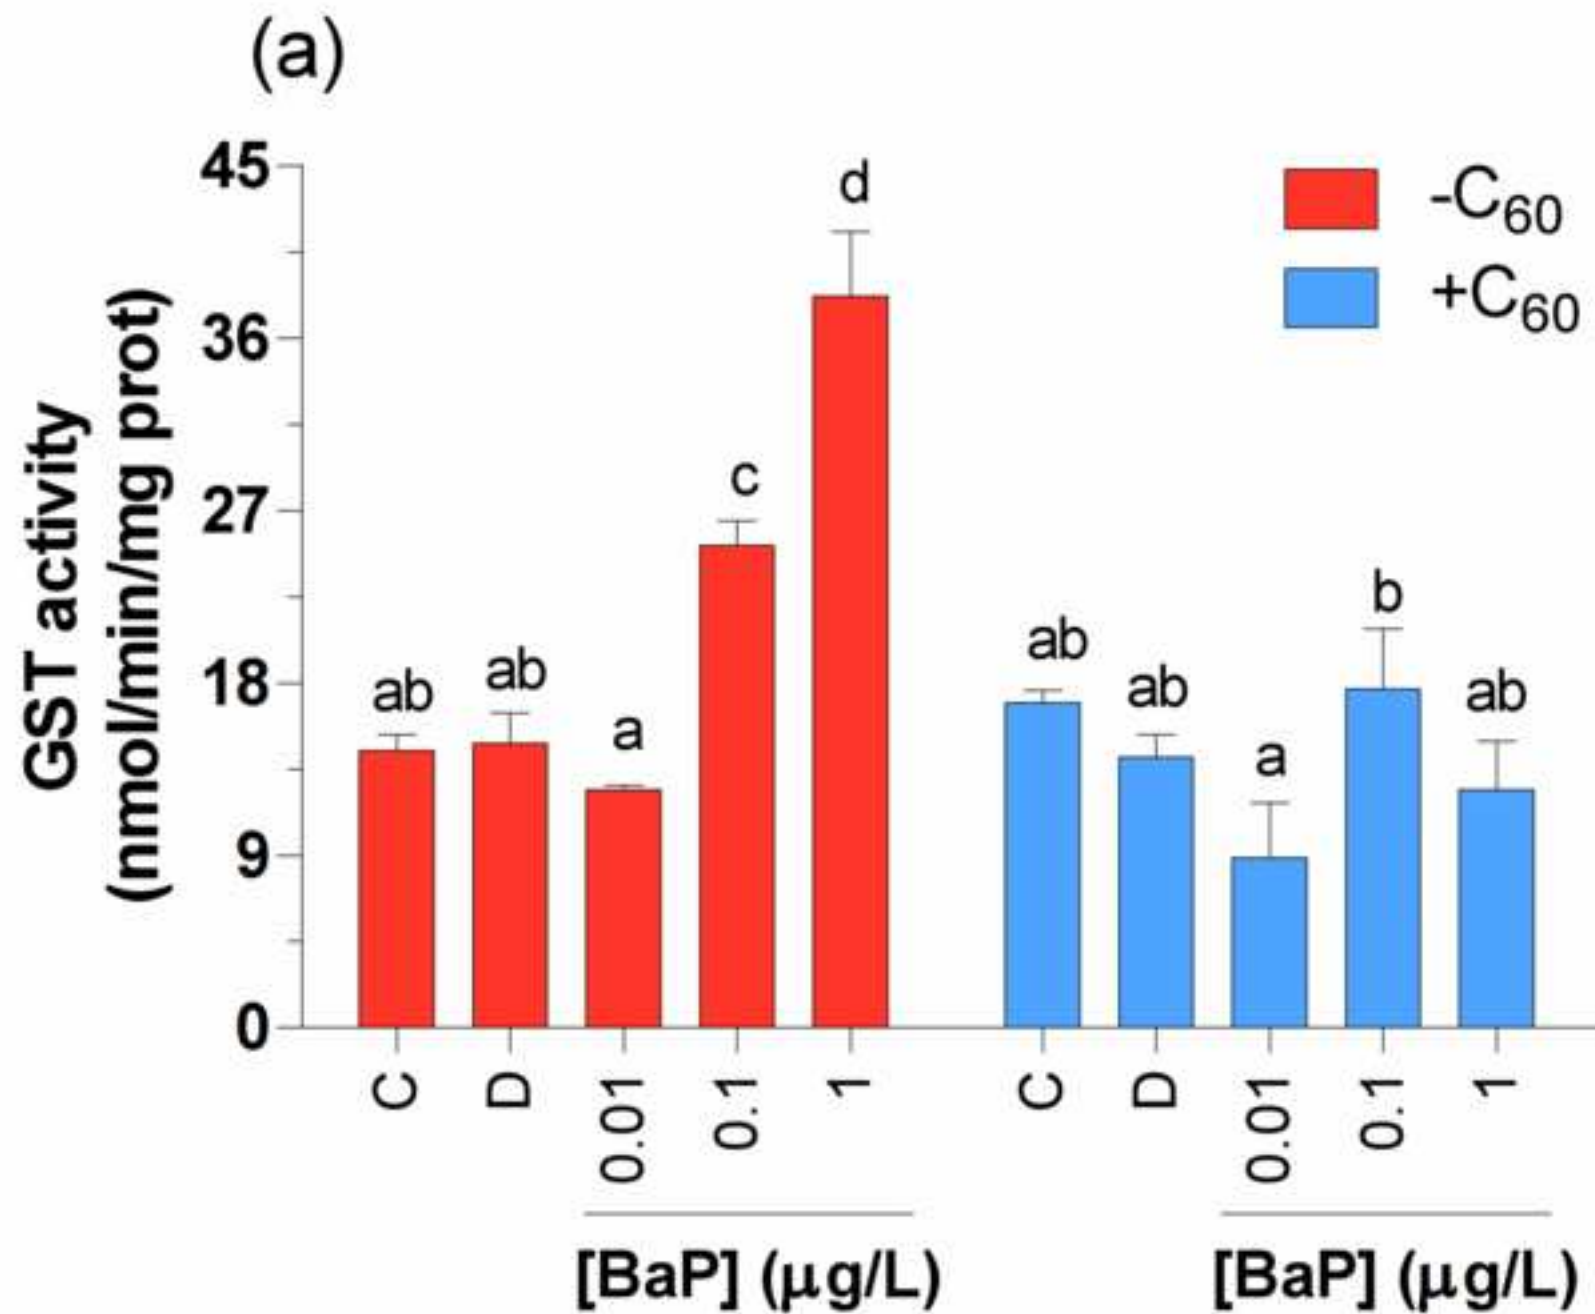

Figure 6

Highlights

- Fullerene C₆₀ and PAH benzo[a]pyrene (BaP) synergistic effects were tested.
- C₆₀ increased cellular intake of BaP.
- C₆₀ decreased cell viability and phase II detoxificatory response triggered by BaP.
- *In silico*, C₆₀ molecule can inhibit the enzyme glutathione-S-transferase.
- C₆₀ can increase toxicity of PAHs possibly through delivery mechanisms.
